GridSQL Planning Guide

1 Introduction

1.1 Purpose

The purpose of this document is to provide information to users of EnterpriseDB GridSQL to allow them to properly plan for its installation and configuration. To help achieve this, hardware purchasing considerations and database schema are discussed.

1.2 Overview

GridSQL is a parallel, clustered database system designed for data warehousing solutions. Its objective is to allow queries involving large volumes of data to execute in parallel across multiple servers in order to return results back more quickly.

The software utilizes other systems, called nodes, each of which houses its own independent database. Each underlying database is Postgres Plus 8.3 or later, or PostgreSQL, running in a shared-nothing architecture, typically using commodity PC-based hardware.

To allow for quick response times, the database administrator (DBA) employs strategies to partition each table in the database, typically based on a computed hash of a column. The optimizer intelligently recognizes when to join tables locally or when it needs to send data to other nodes. Various other techniques are used to achieve linear or near-linear scalability.

EnterpriseDB™

GridSQL Planning Guide

2 Platform

2.1 Operating System

We recommend using Linux as the operating system that the nodes will run on, although we do not recommend any particular distribution.

2.2 Environment

GridSQL is written in Java and communicates with the underlying databases via JDBC. Java Runtime Environment 5.0 or later is required. At the same time, user applications can connect to GridSQL with EnterpriseDB client drivers for JDBC or ODBC, or with any PostgreSQL compatible driver.

Although EnterpriseDB GridSQL runs in a Java Virtual Machine, it should be pointed out that most of the resource intensive work is done within the native underlying databases, with GridSQL coordinating the work.

GridSQL has a single process that executes on the coordinator node. In a simple configuration, the other nodes merely have the underlying database utilized. For greater scalability, a GridSQL Agent process may execute on each node.

2.3 Hardware

Typically PC-based servers are used, due to cost. More detailed information appears in the Hardware Considerations section.

GridSQL Planning Guide

3 Hardware Considerations

3.1 Introduction

A discussion of what to consider when purchasing hardware appears below, along with some recommendations.

3.2 Nodes

Within a node there are various components that influence the total performance of the system, in particular, the CPU, memory, the bus speed, networking components, and storage.

Note the order of the list just stated is in approximate order of the fastest to slowest components. Hard disks are electro-mechanical devices with moving parts and are much slower than CPUs of course.

We also want to avoid making any single component a bottleneck and achieve some balance on each system, but while doing so at a reasonable cost.

3.2.1 Storage

The nodes in the GridSQL cluster will need to read from disk often. To achieve good performance, you should consider using RAID, such as RAID 10 (striping and mirroring) or RAID-5 (striping with parity), with a good disk controller. This allows you to get multiple drives working at the same time. If the SCSI interface is used, you may want to get a controller card with multiple channels to achieve greater data transfer rates from the drives. SATA drives also offer a very good value.

We are mainly concerned with read performance. In addition to read performance gains through striping, the other advantage of using RAID is redundancy. In a RAID-5 or RAID 10 (1+0) configuration, you can achieve both greater throughput through multiple drives, while allowing the node to be able to continue working if there is a drive failure. With many nodes and drives in your cluster, you will likely have a drive failure at some point, so using RAID should be considered a necessity.

Another option is to use software RAID, which appears to be gaining more proponents recently, given the ever-faster processors available.

The drives themselves should have a reasonably fast seek time. You may consider purchasing drives with a high RPM rate.

GridSQL Planning Guide

You can either have direct attached storage, or make use of a SAN. Using a SAN also has the benefit of potentially preparing stand-by nodes for better availability.

You should consider having separate devices for temp space, apart from where table data is stored. GridSQL allows you to define tablespaces, where a logical tablespace group maps to tablespaces on each of the nodes. You can also use this in determining placement of your tables as well. This same device can be used when configuring the PostgreSQL parameter temp_tablespaces.

If indexes are used, you may also want to consider putting indexes on a separate device.

3.2.1.1 Storage Requirements

When deciding on how many individual nodes you want with how many hard disks for each, you should have a good idea of the size of your database. Take into account any indexes that you may create. If you replicate tables or denormalize data, you will need more space (more information on denormalization appears in the Database Schema section). Finally, you should have a lot of extra space for temp tables. GridSQL uses temp tables to store intermediate results as queries are processed. It is recommended to not use more than 60% of the available database storage on a node, but this will vary depending on your schema and queries.

3.2.2 Networking / Interconnectivity

A lot of data will be moving around amongst the nodes, so high-speed connectivity is required between them. Gigabit Ethernet offers the best value in accomplishing this. There are other alternatives such as fibre channel, but it is more expensive.

3.2.3 Memory

One of the most important ways to get more performance out of a system is to have ample memory. More memory allows the database to use more cache. More cache means more of the database can be stored in memory, reducing disk accesses. A caveat here is that for large volumes of data and data warehousing queries that need to scan entire tables, cache rates may be low. Nonetheless, ample memory is a necessity, and helps out tremendously with internal processing such as sorting and intermediate results.

When purchasing your systems, get as much memory as you can within your budget. Keep in mind that it is not just the underlying tables in the database that will use it. Temporary tables will be created and more memory will be available for them as well means less swapping to disk.

GridSQL Planning Guide

3.2.4 CPU

When deciding on a CPU, it is usually best to look for the best performing one at the most reasonable cost. Very often the very fastest available will only offer minor improvements in speed while costing significantly more than a processor slightly slower. You may be better off spending your hardware budget elsewhere.

The coordinator should be a multi-core or multi-processor system.

3.3 *The Coordinator*

You will designate one of the nodes as the coordinator. This is also typically where metadata information is stored. The load will be a little heavier on the coordinator, so it is a good idea to consider getting extra memory and perhaps a multi-core or multi-processor system for the coordinator.

3.4 *Networking / Interconnectivity*

As mentioned above for the nodes, Gigabit Ethernet over copper offers the best value. If you choose that, accordingly, you will want to purchase Gigabit Ethernet switches.

You may want to consider configuring the nodes in the cluster on their own subnet, for better security, while making the non-coordinator nodes accessible only to the coordinator.

GridSQL Planning Guide

4 Database Schema

4.1 Introduction

One of the most critical factors in designing your decision support database is the database schema you chose. Due to the nature of how GridSQL works, we want to allow for as much parallelization as possible. Strategies for achieving this appear below.

Our examples use tables from the TPC-H test schema to better demonstrate various options, with lineitem acting as a fact table.

4.2 Tables

4.2.1 Replicating Tables

Replicating in this context refers to creating an exact duplicate of a table on all of the nodes. We want to do this for smaller lookup tables, like a state_code table containing all of the states in the United States. It would not make much sense to partition a table like this that just has 50 rows. We will spend a lot of time unnecessarily copying them around. It is best to just keep a copy of the table on all nodes. We can do this by using the REPLICATED clause in the CREATE TABLE statement.

Example:

```
CREATE TABLE region (  
  r_regionkey integer not null,  
  r_name      char(25) not null,  
  r_comment   varchar(152)) REPLICATED
```

Now, when region is joined with another table in the query, the join can take place locally on each node in parallel immediately, without having to worry about shipping rows around.

If you have a multi-dimensional schema, you should consider replicating your dimension tables.

GridSQL Planning Guide

4.2.2 Internode Partitioning

In order to achieve fast query times involving large tables, we want to keep all of the nodes busy working while a query is executing. To do that, we want to distribute data in a given table across all of the nodes.

To best explain how this works, some examples are used.

With the CREATE TABLE statement, the DBA can specify how he or she wants to partition the table. This consists of specifying a column and on which nodes to distribute the data. For example:

```
CREATE TABLE orders (  
  o_orderkey    INTEGER NOT NULL,  
  o_custkey     INTEGER NOT NULL,  
  o_orderstatus CHAR(1) NOT NULL,  
  o_totalprice  DECIMAL(15,2) NOT NULL,  
  o_orderdate   DATE NOT NULL,  
  o_orderpriority CHAR(15) NOT NULL,  
  o_clerk       CHAR(15) NOT NULL,  
  o_shippriority INTEGER NOT NULL,  
  o_comment     VARCHAR(79) NOT NULL) PARTITIONING KEY o_orderkey  
ON ALL
```

“ON ALL” here indicates that all nodes defined for the available cluster should be used. We could have also specified a subset of nodes by giving their node id numbers as well. In practice, it makes sense to utilize all of the available nodes, unless you are using a dedicated coordinator and wish to keep partitioned data off of it.

The partitioning key in the example is o_orderkey. A hash will be calculated based on o_orderkey’s value for each row and will be mapped to one of the nodes to determine where the row will reside. An even distribution across all nodes will be achieved.

Now, if we were to execute a singleton SELECT such as

```
SELECT * FROM orders WHERE o_orderkey = 1000
```

GridSQL will recognize that o_orderkey is the partitioning key, and will calculate a hash value to determine which node is responsible for value 1000. It will then obtain the data only from the single, required node.

In your decision support environment, you will more likely be executing larger queries, like

```
SELECT MAX(o_totalprice)  
FROM orders
```

GridSQL Planning Guide

```
WHERE o_orderdate >= '01/01/2003'
```

This type of query scales very well. In this case, GridSQL will execute that exact same query on each of the nodes. In a 16 node system, it will receive 16 different results, each of which is the MAX(o_totalprice) that is on the particular node. It will then take the MAX value of those 16 results, to arrive at the final MAX result.

GridSQL Planning Guide

4.2.3 Constraint Exclusion Partitioning

Note: this is different from GridSQL's internode partitioning.

Postgres Plus Advanced Server possesses the ability to "partition" within a database instance via check constraints. This allows the DBA to create segments for a table that contain ranges of values, for example. A table named orders could be partitioned into monthly subtables, allowing queries that include a condition based on order date to scan with a smaller set of data, and therefore have a faster query time.

This is a powerful feature that should be taken advantage of. Constraint exclusion partitioning coupled with GridSQL's partitioning across multiple nodes will result in significantly faster query response times; a large table can be broken into multiple subtables, each of which is partitioned across multiple nodes in the GridSQL cluster.

An example appears below.

```
CREATE TABLE orders (
  o_orderkey      INTEGER NOT NULL,
  o_custkey       INTEGER NOT NULL,
  o_orderstatus   CHAR(1) NOT NULL,
  o_totalprice    DECIMAL(15,2) NOT NULL,
  o_orderdate     DATE NOT NULL,
  o_orderpriority CHAR(15) NOT NULL,
  o_clerk         CHAR(15) NOT NULL,
  o_shippriority  INTEGER NOT NULL,
  o_comment       VARCHAR(79) NOT NULL)
PARTITIONING KEY o_orderkey ON ALL;

CREATE TABLE orders_199201
( CHECK (o_orderdate BETWEEN '19920101'::DATE AND '19920131'::DATE) )
INHERITS (orders);

CREATE TABLE orders_199202
( CHECK (o_orderdate BETWEEN '19920201'::DATE AND '19920228'::DATE) )
INHERITS (orders);

:
```

Any query like "SELECT count(*) from orders where o_orderdate between '1992-01-01' and '1992-01-15'" will only use tuples found from the orders_199201 subtable (and the orders table, which should be left empty).

Note that when loading data, you must insert data into the proper subtable. Using the above example, in the current implementation, loading into orders directly will not automatically insert the data into the correct subtable; you must do so directly.

Another important consideration when creating subtables constraints is to be aware that the current implementation is a bit data type sensitive, and you might find that the EnterpriseDB executor is not taking full advantage of eliminating subtables.

GridSQL Planning Guide

In the case of dates, we recommend using the above syntax to cast it a date type, as in

```
CHECK (o_orderdate BETWEEN '19920101'::DATE AND '19920131'::DATE)
```

Leaving it as either just a date, or as a quoted string may cause queries to not be executed optimally. This depends on how the CHECK constraints are formulated and how the WHERE conditions are formulated. The above check constraint syntax handles various date constructs (quoted, cast) in SELECT WHERE clauses properly.

4.2.4 How Joins Affect Partition & Replication Strategy

Now that we have covered some of the basics, some more advanced examples are discussed.

Assume we have the following table, lineitem, which acts as a fact table in our database:

```
CREATE TABLE lineitem (  
  l_lineitemkey INTEGER NOT NULL,  
  l_orderkey   INTEGER NOT NULL,  
  l_partkey    INTEGER NOT NULL,  
  l_suppkey    INTEGER NOT NULL,  
  l_linenumber INTEGER NOT NULL,  
  l_quantity   DECIMAL(15,2) NOT NULL,  
  l_extendedprice DECIMAL(15,2) NOT NULL,  
  l_discount    DECIMAL(15,2) NOT NULL,  
  l_tax         DECIMAL(15,2) NOT NULL,  
  l_returnflag  CHAR(1) NOT NULL,  
  l_linestatus  CHAR(1) NOT NULL,  
  l_shipdate    DATE NOT NULL,  
  l_commitdate  DATE NOT NULL,  
  l_receiptdate DATE NOT NULL,  
  l_shipinstruct CHAR(25) NOT NULL,  
  l_shipmode     CHAR(10) NOT NULL,  
  l_comment     VARCHAR(44) NOT NULL) PARTITIONING KEY l_lineitemkey  
ON ALL
```

We want to execute the following query:

```
SELECT  
  l_orderkey,  
  SUM(l_extendedprice * (1 - l_discount)) as revenue,  
  o_orderdate,  
  o_shippriority  
FROM  
  Orders INNER JOIN lineitem ON l_orderkey = o_orderkey
```

GridSQL Planning Guide

```
WHERE
    l_shipdate > '1994-09-20'
GROUP BY
    l_orderkey,
    o_orderdate,
    o_shippriority
ORDER BY
    revenue desc,
    o_orderdate;
```

Note that a join occurs on `lineitem.l_orderkey = orders.o_orderkey`. Assume that in looking at our table definitions, the table `orders` was partitioned on `o_orderkey`, and `lineitem` was partitioned on `l_lineitemkey`. It could be that a given `o_orderkey` value is on node 7 and needs to join with the equivalent `l_orderkeys` on nodes 4, 9 and 13. Since they are on different nodes, GridSQL will need to ship data around for joining. While we take advantage of all the nodes we have and it will execute fine, it will not be as quite as fast as if the needed rows were on the same node.

Now assume that `l_lineitem` was instead partitioned on `l_orderkey`. In this case, GridSQL will recognize that the join condition occurs on expressions that match the partitioning scheme of the tables involved. It will therefore perform the join locally on each node, instead of needing to ship rows.

This example illustrates the importance of choosing good partitioning keys. Although the database may be used in environments where ad-hoc querying tools are available, the DBA should try and choose sensible partitioning keys for joins that are likely to occur.

As previously mentioned, if you have a multi-dimensional schema, you should consider replicating your dimension tables. If you have a particularly large dimension table that is used often with a fact table, you may want to partition both of these on their respective join keys.

4.2.4.1 Another Example

We will examine another more complex example. It is somewhat contrived, as well as with some possible alternatives discussed, just to illustrate things to consider when determining how to determine your schema and partitioning.

```
SELECT
    c_custkey,
    c_name,
    sum(l_extendedprice * (1 - l_discount)) as revenue,
    c_acctbal,
    n_name,
    c_address,
    c_phone,
```

GridSQL Planning Guide

```
c_comment
FROM
customer INNER JOIN orders ON c_custkey = o_custkey
INNER JOIN lineitem ON l_orderkey = o_orderkey
INNER JOIN nation ON c_nationkey = n_nationkey
WHERE
    o_orderdate >= '1994-07-01'
AND o_orderdate < '1994-07-02'
AND l_returnflag = 'R'
GROUP BY
c_custkey,
c_name,
c_acctbal,
c_phone,
n_name,
c_address,
c_comment
ORDER BY revenue desc;
```

Assume that nation is REPLICATED on all of the nodes here, with customer partitioned on c_custkey, orders on o_orderkey and lineitem on l_orderkey. GridSQL will need to execute this query in a couple of steps. There are various alternatives that the Optimizer will evaluate, including:

- It could join customer and nation first, then join these results with orders and lineitem.
- It could join orders and lineitem first, then join these results with customer and nation.

The join pairs customer-nation and orders-lineitem can each take place at the individual nodes without row shipping occurring. The customer-nation join involves nation, a replicated look-up table, so no rows need to be shipped. The orders-lineitem join involves a parent-child join, so no rows need to be shipped here either.

In either case, there is an intermediate step of rows having to be shipped. The query will scale well, however. Consider the case where customer is replicated. If that were the case, we could perform a join on all 4 of the tables at once locally at the nodes and eliminate the additional step.

Replicating customer on all of the nodes will help in cases like this, but there are things to consider and trade-offs.

- The cardinality of orders to customer and the number of nodes. This may influence how close to linear the query can scale as more nodes are added.
- The other expected queries. If users perform a lot of queries only against the customer table without joining with others, it will be executed on just one node instead of others, and you lose parallelism. Also, joins will occur against a bigger table on each node, whatever the join columns may be. In cases like this, it is probably not a good idea to replicate.

GridSQL Planning Guide

- Note that if there are a lot of queries just against this single customer table, another alternative would be for the DBA to set up two customer tables; one that is replicated and one that is partitioned. It is up to your ETL process to load up both tables. Also, reports that users run will have to choose the appropriate table.

We could have also set up our schema so that o_custkey is the partition column for orders. The drawback to that though is that lineitem can no longer be joined locally with orders on l_orderkey without shipping rows.

To summarize, there are various considerations and trade-offs to weigh when choosing your schema. It is also best to be familiar with the types of queries that will be run against your database to guide decisions. Finally, the schema you decide on will influence your ETL process to ensure data is loaded up properly.

4.2.5 Dimensional Data Modeling

One should focus on creating a dimensional data model with facts and dimensions. It is recommended that smaller dimension tables be designated as REPLICATED. That is, an exact copy of each table appears on all of the nodes. In this way, there is no need to ship this data around constantly. The meaning of “small” will depend on the total size of the data warehouse, but if you have large fact tables with millions of rows, dimensions with less than 100,000 rows should be replicated. If you have facts with billions of rows, dimensions with row counts even up to seven figures may be replicated.

If you have a particularly large dimension table, you may want to partition fact tables that join with it on the foreign key that it uses to join with that dimension table, as well as partition the dimension table itself on its primary key. This way, all joins take place locally without any row shipping.

4.3 The Role of the Coordinator

The Coordinator does a bit more work than the other nodes in the system. It performs the optimization and query planning, as well as directs the execution of the query, synching up instructions for work going on at other nodes.

With this in mind, you may want to consider making one node a dedicated coordinator, particularly if your system has 8 or more nodes. A coordinator that is dedicated would guide the queries on the other nodes but does not participate in them.

Coordinators can also house replicated tables. This allows for serving quick queries where a reporting app may, for example, get all of the possible values in a look-up table like region, while freeing up the other nodes to do the heavy lifting.

GridSQL Planning Guide

Again, the decision to go with such a configuration largely depends on the number of nodes you have. If just using a 4 node system, it often is not worth having a dedicated coordinator. You could however consider making it slightly more powerful than the other nodes.

GridSQL Planning Guide

5 Redundancy, Backup and Recovery

The current version of GridSQL has no built-in redundancy. Keep in mind that the component most likely to fail is going to be a hard disk, and by using a RAID configuration like RAID 0+1 or RAID-5, you are well protected against such a failure.

GridSQL will typically be used in reporting or data warehousing type of scenarios so while important and will be added, it is not as critical as a high volume OLTP database.

One solution is to rely on HA solutions such as from Veritas or Red Hat.

You could have your data out on a SAN, and have a stand-by node ready to point to the failed node's data. The gridsql.config file would have to be modified for the node, and GridSQL stopped and restarted.

You can also replicate the metadata database and user-created databases on the nodes.

For replication, you can rely on EnterpriseDB Replication or Slony for a manual stand-by configuration. Note that any schema changes (ALTER TABLE) may require re-snapshotting the modified table. To failover to a stand-by node, the node information is changed in gridsql.config, and GridSQL is stopped and restarted.

To make efficient use of the nodes in the cluster, you should consider creating the replicated copies of one node on another node. For example, node 1's databases are replicated to node 2, node 2's to node 3, and so on.

The current version relies on the backup and restore programs available for the underlying database, or optionally with the help of GridSQL's utilities. This includes full backups and incremental or log file backups. Individual nodes may be backed up at the same time.
